OFFICE OF TELECOMMUNICATIONS

The Department of Commerce, under the 1970 Executive Order No. 11556, has been given the responsibility of supporting the Government in general and the Office of Telecommunications Policy in particular in the field of telecommunications analysis. The Department of Commerce, in response to these added duties, established the Office of Telecommunications as a primary operating unit to meet the demands of telecommunications in the areas of technical and economic research and analysis. The Office consists of three units as follows:

Frequency Management Support Division: Provides centralized technical and administrative support for coordination of Federal frequency uses and assignments, and such other services and administrative functions, including the maintenance of necessary files and data bases, responsive to the needs of the Director of the Office of Telecommunications Policy (OTP) in the Executive Office of the President, in the performance of his responsibilities for the management of the radio spectrum.

Telecommunications Analysis Division: Conducts technical and economic research and analysis of a longer term, continuing nature to provide information and alternatives for the resolution of policy questions, including studies leading to the more efficient allocation and utilization of telecommunication resources; provides forecasts of technological developments affecting telecommunications and estimates their significance; provides advisory services in telecommunications to agencies of Federal, State and local governments; and performs such other analysis as is required to support OTP.

Institute for Telecommunication Sciences: The Institute for Telecommunication Sciences (ITS), as a major element of the Office of Telecommunications, serves as the central Federal agency for research on the transmission of radio waves. As such, ITS has the responsibility to:

- (a) Acquire, analyze and disseminate data and perform research in general on the description and prediction of electromagnetic wave propagation, and on the nature of electromagnetic noise and interference, and on methods for the more efficient use of the electromagnetic spectrum for telecommunication purposes;
- (b) Prepare and issue predictions of electromagnetic wave propagation conditions and warnings of disturbances in those conditions;
- (c) Conduct research and analysis on radio systems characteristics, and operating techniques affecting the utilization of the radio spectrum in coordination with specialized, related research and analysis performed by other Federal agencies in their areas of responsibility;
- (d) Conduct research and analysis in the general field of telecommunication sciences in support of other Government agencies as required; and
- (e) Develop methods of measurement of system performance and standards of practice for telecommunication systems.

TABULATIONS OF PROPACITION DATA OVER IRREGULAR TERRAIN IN THE 230% to 9200-MID FREQUENCY RANGE

PAR'I IV: Receiver Site in Grove of Trees

P. L. McQuate, J. M. Harman, and M. E. McClanalian

This is the fourth part of a four-part report containing tabulations and graphs of transmission loss data resulting from propagation experiments in the 230- to 9200-MHz frequency range conducted over irregular terrain in Colorado. This part presents data obtained at a common receiver site, located in a small grove of cottonwood (Populus deltoides) trees, over propagation paths varying in length from 0.5 to 50 km.

Key Words: UHF propagation data, irregular terrain, UHF propagation through trees

1. UITRODUCTION

The purpose of this four-part report series is to present tabulations of transmission loss data resulting from propagation over irregular terrain in Colorado with path length ranging from 0.5 to 120 km ac seven frequencies in the 230- to 9200-MHz range.

The measurement program was sponsored by the U.S. Army Electronics Command and the U.S. Army Security Agency as part of a study of propagation characteristics under conditions resembling the operations of an army in the field.

Part 1 of this report series (McQuate, et al., 1968) presented data obtained at a common receiver site (R1) located near the summit of a till in the open plains, about 15 km northeast of Boulder. Several of the transmitting sites associated with this common receiver site were located in the mountains west of Boulder and east of the

1

continental divide; all others were located in the relatively open and rolling plains area. This part includes also a more complete description of the equipment used, and of data collection and measurement techniques.

Part II of this series (McQuate, et al., 1968) presents data obtained at a common receiver site (R2) located in the mountains near Rollinsville, about 20 km southwest of Boulder. The mountains shield this site from the plains. Only eight of the 44 transmitting sites associated with this receiving location are in the plains area.

Part III (McQuate, et al., 1970) presents data obtained at a common receiver site (R3) located on the eastern edge of a high mesa at a juncture between the mountains and plains near Golden, about 25 km south of Boulder. This site was selected to represent propagation from ground to low-flying aircraft. All of the 57 transmitting sites associated with this receiver site are located in the relatively open and rolling plains area.

This, the fourth part of the four-part report series, presents data obtained from common receiver site R4, located in a cluster of trees in in the broad St. Vrain Creek valley near Longmont, about 25 km northeast of Boulder.

Figure 1 is an aerial photograph of the area. The receiver antenna tower is located near the center of the left edge of the largest tree cluster. A white cross was placed at the top of the tower to help locate it in the aerial photograph and it also serves as the northern terminal of a true north-south line. The southern terminal of this line is a white cross on the ground shown near the bottom edge of the photograph. The dark area, near the cross marking the top of the tower, is the area where the tree foliage was removed to permit unobstructed vertical movement of the receiving antennas.

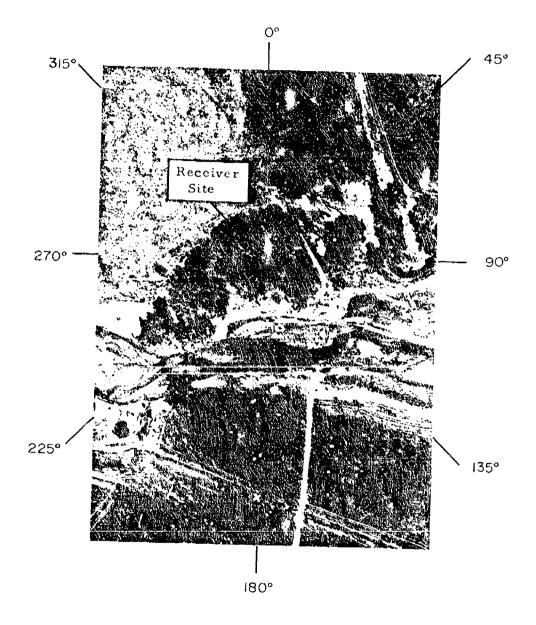

Figure 1. Aerial view of the common receiver site. Azimuths in degrees from true north.

All path loss measurements were made at the fixed receiving site using mobile transmitters. Received signal levels were recorded continuously as the receiving antennas were raised from near ground to a point well above the top of the trees; therefore, the received signal levels reflect, to a varying degree, the effects of toliage and branches on the electromagnetic field.

2. MEASUREMENT PROGRAM

Figure 2 presents an overall view of the measurement area and shows for clarity only 27 of the 36 transmitter locations. Most of those not shown are within 10 km of the common receiver site. The measurement points are arranged around the common receiver in concentric circles at nominal distances of 0.5, 3, 5, 10, 20, 30, and 50 km.

Figures 3, 4, and 5 are panoramic views of the measurement area as seen from the top of the receiving antenna tower (26.8 m above ground) and figures 6, 7, and 8 are views of the trees as seen by the receiving antennas 1.5 m above ground. Maximum leaf cover begins about 7 m above ground and continues to the top of the trees. Figures 3 and 5 show that the trees are of uniform height, approximately 18 m above ground. No transmitting sites were located in the west-to-northeast sector between approximately 270° and 40° true azimuth.

All except two transmitting sites lie in the relatively open and rolling plains area east of the mountains, and, unlike the transmitter sites used in earlier reports of this report series, all transmitter sites were selected to provide a clear and unobstructed foreground in the direction of the receiving antenna.

Signals were recorded for the six frequencies from all 36 transmitting sites while the leaves were on the trees and then the measurements were repeated after the leaves had fallen from the trees and the trees were dormant.

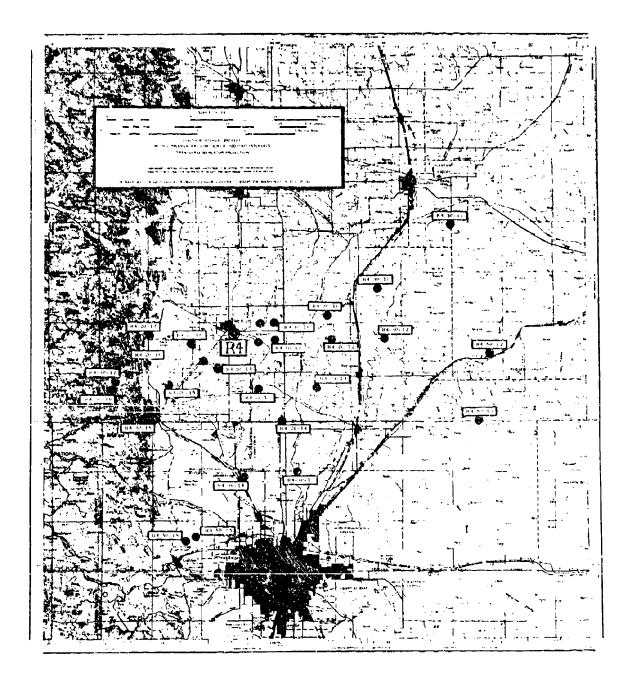

Figure 2. Layout of transmitter sites in relation to the common receiver site R4.

or from 1.5m above the ground.

r from 1.5 in above the ground.

All transmissions were continuous wave and frequencies of 230, 410, 910, 1846, 4595, and 9190 MHz were used with horizontal polarization. However, at the conclusion of the measurement program, additional measurements were made from three of the transmitter sites (R4-10-T5, R4-20-T6, and R4-30-T6) on 230 and 410 MHz, using horizontally polarized, vertically polarized, and cross polarized antennas in order to evaluate the polarization losses caused by trees without leaves. These transmitter sites were in the direction of maximum tree depth as seen from the receiver site (bearing 235° true, see figure 1). Finally, an elevated transmitter site (Test Site), also in the direction of maximum tree depth at the receiver site, was selected to provide an unobstructed path between the transmitting antennas and the cluster of trees surrounding the receiver site. The data resulting from these measurements are shown in the Appendix.

3. RECEIVING EQUIPMENT

The six frequencies were divided into two groups and separate receiving and transmitting vans were outfitted for each group. Although seven frequencies had been used for the measurements reported in the three preceding parts of this report series, the 751-MHz equipment was seldom employed at the R4 site because of operational problems. Thus, path loss data are not available for this frequency. Figure 9 shows the low-frequency group (230, 410 and the inoperative 751 MHz) receiver trailer at common receiver site R2, and figure 10 shows the receiver trailer used for the four higher frequencies (910, 1846, 4595, and 9190 MHz) at common receiver site R3. Both figures show the antennas associated with each frequency group mounted on a movable carriage attached to identical towers, and the same installation was used for the R4 measurements reported here. The carriages could be installed on any of the four tower faces and raised or lowered between the limits of

1 and 25 m above ground for the low-frequency group, or 1 and 24.5 m for the nigher-frequency group, both at a speed of approximately 0.6 m/sec. A servo system on the antenna carriage drove a strip-chart recorder for the continuous signal strength versus antenna height recordings.

Propagation data were obtained between August 2 and September 30, 1966 (when the leaves were on the trees) and between November 11, 1966 and March 14, 1967 (when trees were without leaves).

Identical transmitting and receiving antennas were used for each frequency group, and the electrical characteristics of each pair were essentially identical; parameters are given in Table 1. The VSWR of the antenna systems, as viewed at the receiver input, exhibited essentially no change as the antennas were moved up and down the tower; thus we believe that effects of the immediate environment on the antenna impedance can be neglected.

4. TRANSMITTING EQUIPMENT

The transmitting equipment was contained in two vans; one, for the two lower frequencies, the other for the four higher frequencies. Figures 11 and 12 show the vans. The antennas were mounted side by side on a framework attached to a rigid mast that pivoted in elevation and azimuth on a base mounted on top of the vans. This arrangement assured constant antenna height above ground for each frequency group (6.6 m for the lower frequency group and 7.3 m for the higher). After the antenna assembly had been raised and before transmission, the antennas were oriented to the path azimuth by sighting through a device on the mast, if the receiver location was visible, or with the aid of a magnetic compass, corrected for magnetic declination, when the receiver location was obscured.

5. DATA PRESENTATIONS AND TABULATIONS

The data, except for antenna polarization and patterns, are arranged

Table 1. Antenna Parameters

Freq. in MHz	1/2 Power Beamwidth	Description	Free-Space Gain Above Isotropic, dB	Height Above Ground, m Transmitting Receiving	Ground, m Receiving
230	380	half-wave center-fed dipole with reflector	6*9	9.9	1-15 (continuously variable at all frequencies)
410	58°	three-element Yagi with reflector	8.6	9.9	•
751	o69	half-wave center-fed folded dipole with reflector	6.7	9.9	
910	52 . 5 ⁰	four-element Yagi with reflector	9.1	7.3	
1846	330	horn	15.2	7.3	
4595	12.59	horn	19.7	7,3	
9190	12.50	horn	21.0	7.3	

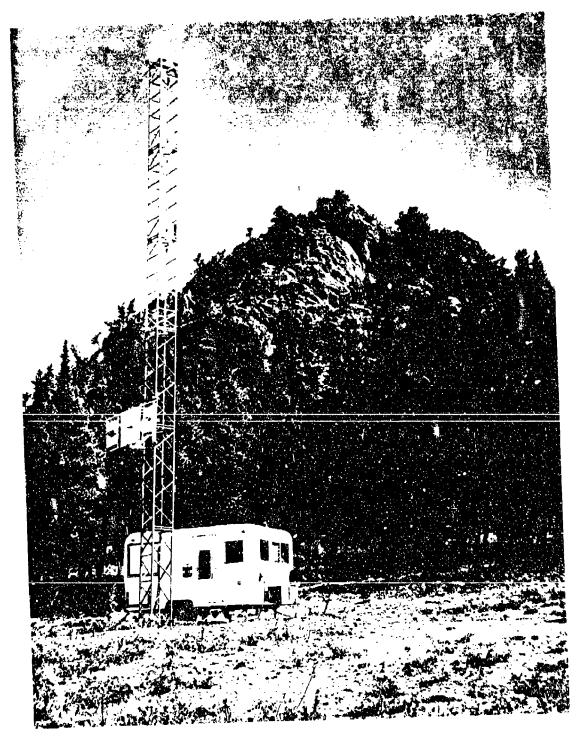

Figure 9. The lower frequency group receiving equipment at common receiver site R4.

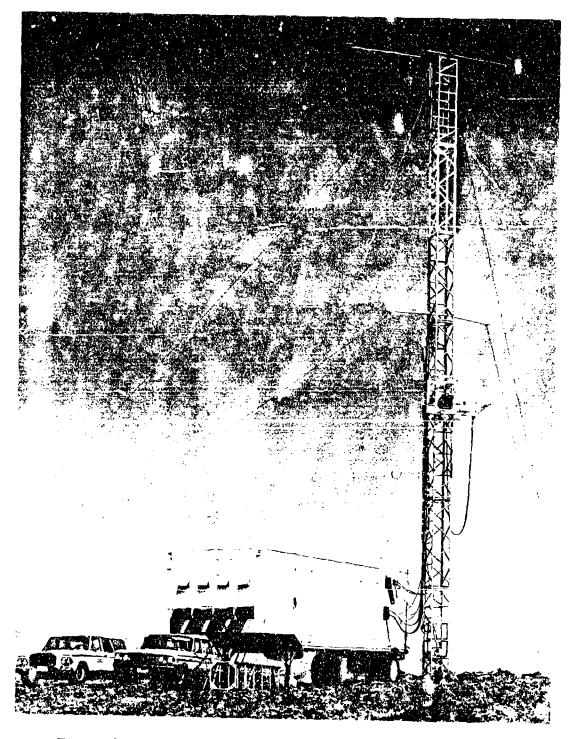

Figure 10. The upper frequency group receiving equipment at common receiver site R4.

Figure 11. Lower frequency group transmitting unit.

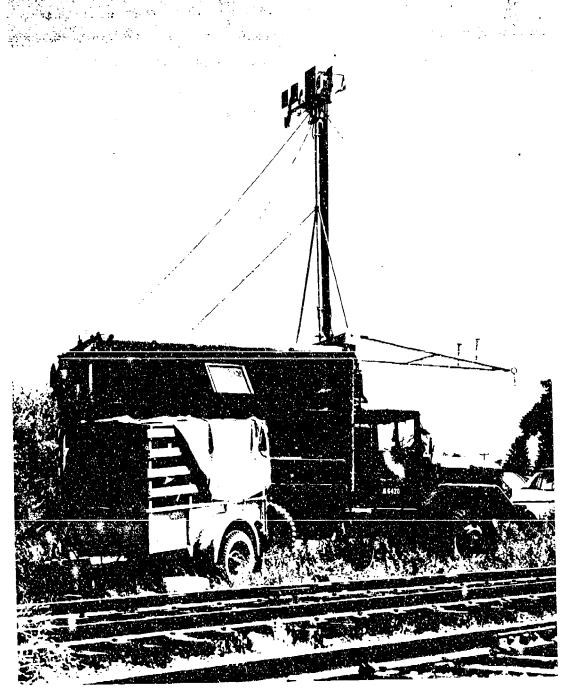

Figure 12. Upper frequency group transmitting unit.

as in Parts I, II and III of this report series; i.e., by path distance and for each distance sequentially by azimuth counted clockwise from true north. For example, R4-20-T2 indicates a 20-km path (nominal length) from the receiver site R4 to transmitter site T2, which is the second transmitter site at the 20-km distance counted clockwise, from true north. However, some of the proposed transmitter locations were inaccessible, or otherwise unsuitable, and other points had to be substituted. Particularly, sites R4-30-T5 and R4-30-T7 are at distances less than 25 km. The actual path lengths rather than code designations will be used in any subsequent analyses of the data but it is not practical to revise the numbering scheme. The data for each transmission path are arranged in the following order: The first page includes the site designation and code, a photograph of the terrain taken at the transmitter site in the direction of the receiver, and the true bearing from the receiver site to the transmitter site.

The next page contains the site designation and code, a graph of basic transmission loss vs. receiving antenna height and the date when each frequency group was measured. Only data taken with the leaves on the trees are shown here. Also indicated are the free-space basic transmission loss for each frequency and the level of the maximum measurable loss if the received signal level was below the receiver noise level. The graphs of basic transmission loss vs. antenna height were obtained directly from computer storage by a cathode ray tube plotter, and only a limited number of distinct line symbols were available. In most cases it is not difficult to identify and follow the traces for the various frequencies.

Part I of this report series (McQuate et al., 1968) includes a discussion of the assumptions used (including formulas, parameters, etc.) to correct receiver power level values to basic transmission loss.

A number of these graphs do not show curves for all six frequencies.

This is because of equipment malfunction, temporary inaccessibility of the transmitter sites, calibration errors, or misalignments of antennas.

The third page shows the site code and includes the following:

- (a) The path profile, with site elevations and path length, is drawn by using an effective earth radius (a = 8330 km) based on an area average surface refractivity value of 290 N-units. The effective earth curvature is illustrated by an arc drawn arbitrarily through the second elevation mark in the center of the profile. This arc represents the intersection of a surface parallel to the earth's surface with the plane of the paper and provides a reference line for assessing relative elevation along the terrain profile. Note that horizontal and vertical scales are not constant for all terrain profiles. The scales were chosen to provide maximum clarity within the available space, and the effective earth radius concept requires a fixed relation between horizontal (distance) and vertical (elevation) scales to permit radio rays to be represented as straight lines.
- (b) The results of the time recording, obtained just prior to each height-gain run, shown below the path profile and designated " L_b (dB) short-term signal variability". The 50 percent value is defined as the basic transmission loss value, in decibels, exceeded 50 percent of the time during the 10-min time recording period. The $\Lambda 10\%$ 90% value is defined as the decibel difference between the level of the received signal exceeded for 90 percent of the time during the recording period and the level exceeded only 10 percent of the time during the same period.
- (c) Field notes describing the terrain and significant obstacles along the transmission path, as seen by an observer at the transmitter site. The field notes reflect the operator's observations particularly with regard to foreground while the terrain characteristics are shown more exactly by the profiles.

Additional pages include graphs of basic transmission loss vs. receiving antenna height derived from path loss measurements over a common path with the trees in full leaf (late summer) and after the leaves had fallen (winter). Data are plotted in pairs for each frequency for each transmitting site. Time run data for the winter measurements, similar to the time run data described earlier, follow the graphs of the transmission loss curves for each transmitter site.

6. ACKNOWLEDGEMENTS

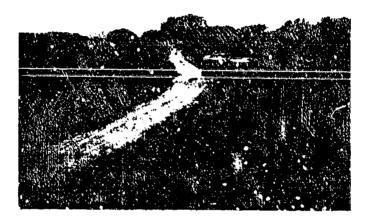

All personnel within the former Tropospheric Radio Systems Predictions Group of the Institute for Telecommunication Sciences participated in the collection, analyses and evaluation of the data.

8. TABULATION OF DATA

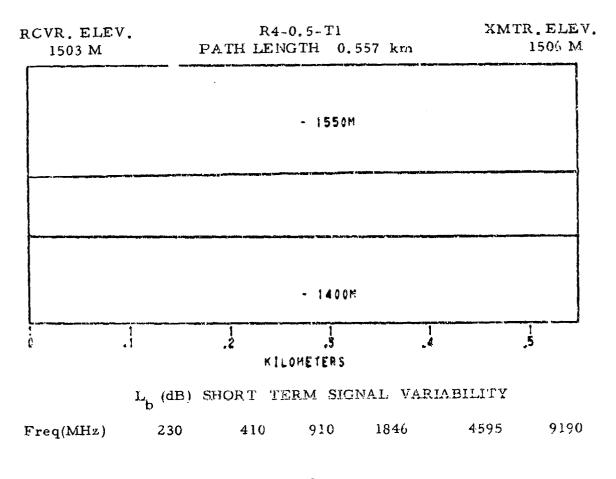

Propagation data tabulations are presented on pages 21 through 265. Figure numbers in this section have been omitted since all data, pictures, and graphs are identified by the appropriate site code number.

PATH VIEW FROM TRANSMITTER Bearing from common receiver site to transmitter site is 269° 41' 04"

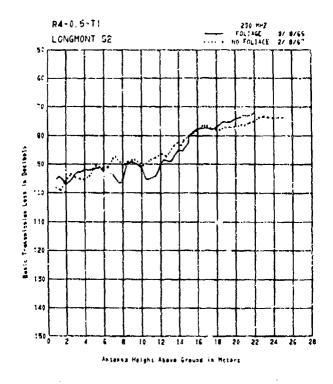

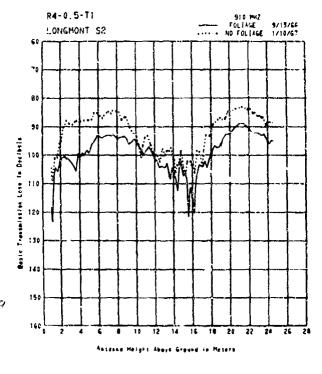

Antenna Height Above Ground in Meters

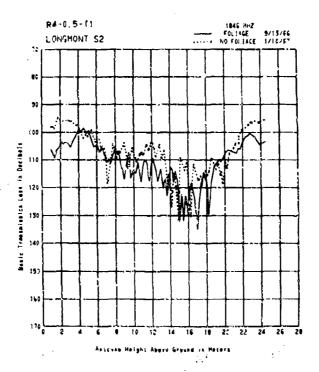

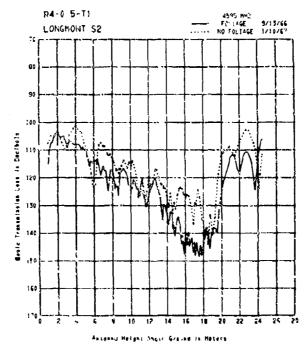

No data available.

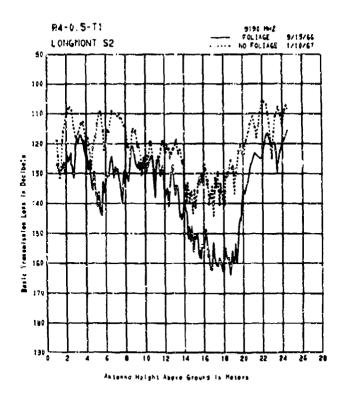

The radio path extends over open, grassy land. A barbed-wire fence, 1 m high, runs beside a dirt road and slightly to the left of the path. Two deciduous trees, approximately 20 m high, stand directly in the path, about 150 m from the transmitter.

9. METEOROLOGICAL INFORMATION

This section of the report presents a comprehensive listing of meteorological parameters for each path that were obtained simultaneously with the path loss measurements. Wet and dry bulb temperatures were obtained by reading electrically operated psychrometers; atmospheric pressures were indicated on high-grade aneroid barometers; percent relative humidity was calculated from data obtained at the site. Cloud types were based on the National Weather Service cloud code classification, and percent cloud cover, wind speed, and wind direction were estimated.

APPENDIX

At the conclusion of the path loss measurement program, additional measurements were made over selected paths (R4-10-T5, R4-20-T6, and R4-30-T6) to evaluate polarization (including cross polarization) losses caused by trees without leaves. Measurements were also made, using a slightly elevated transmitter test site, to investigate the azimuthal angle-of-arrival of the 230 and 410-MHz signals for several receiving antenna elevations at the R4 receiving site.

All the transmitter sites for this series of measurements were selected to provide maximum shielding of the receiving antennas from the transmitting antennas by the cluster of trees at the R4 receiving site. The true bearings of these transmitter sites from the receiver site are: R4-10-T5, 227° 20'; R4-20-T6, 250° 07'; R4-30-T6, 234° 47'; and Test Site, 234° 48' (see figure 1).

The polarization data were collected using the same measurement techniques developed for the original path loss measurement program. However, before any measurements using vertical polarization were attempted, all inactive antenna dipoles in the antenna array were removed from the front of the antenna reflector screen (see figures 9 and 11 for physical appearance of the lower frequency antennas), thus preventing the possibility of interaction between the active and inactive elements.

Cross polarization measurements were made by changing the receiving antenna polarization with respect to the transmitting antenna except for site R4-30-T6, where both antennas were rotated 90 degrees with respect to each other.

The azimuthal angle-of-arrival data were obtained by raising the receiving antenna to the desired height above ground and recording the received signal level as the receiving antenna was turned in azimuth,

in 10-degree steps, from a position 60 degrees counterclockwise to the transmission path to a point 60 degrees clockwise to the path. This procedure was then repeated for all other receiving antenna elevations for both frequencies.

The data for the supplemental polarization measurements are arranged in the following order:

For the polarization measurements, graphs of basic transmission loss versus receiving antenna height derived from the path loss measurements are shown for each of the three paths for both frequencies with site code and designation, frequency, date, and foliage condition indicated on each. The type of polarization used is shown for each graph with the receiving antenna orientation indicated first; i.e., V-H indicates that the receiving antenna was oriented to receive a vertically polarized signal and the transmitting antenna was oriented to transmit a horizontally polarized signal. For conversion of the measured values to basic transmission loss the antenna gain values shown in table 1 (section 4 of the report) were used, although they may not be realistic for cross polarization measurements. The "basic transmission loss values" resulting from this procedure should therefore be used only for relative comparisons. Generalization of these results to other antenna types may not be appropriate.

The free space basic transmission loss is indicated on each graph. Photographs of the terrain taken at the transmitter site in the direction of the common receiver site and the bearing from the receiver site to the transmitter site may be found under the corresponding site in the main body of the report.

Arrangement of the data (see pages 293-296) for the azimuthal angle-of-arrival measurements (designated Test Site) is as follows:

The first page includes the site code, a photograph of the terrain taken at the transmitter site in the direction of the receiver, and the bearing from the common receiver site to the transmitter site. It also includes the ground elevation of the receiver and 'ransmitter sites, the actual path length, and the path profile drawn as previously described for other paths.

The second page includes the site designation and code, a code for the graph for each frequency, followed by the date that the path loss measurement was undertaken, a graph of the 230 and 410 MHz basic transmission loss versus receiving antenna height (data for these graphs were obtained by measurements techniques previously described), and the free space basic transmission loss for each frequency.

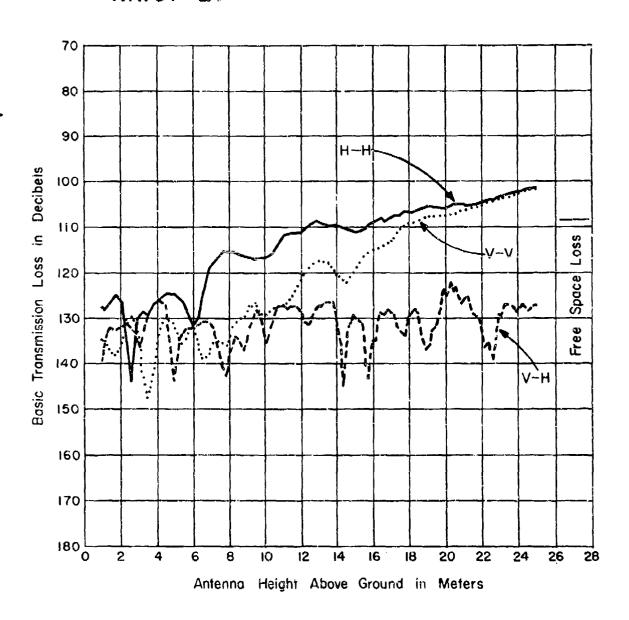

The upper set of graphs on the third page includes plots of basic transmission loss versus receiving antenna orientation with respect to the transmitting path for several receiving antenna elevations. These graphs are for horizontal polarization for 230 MHz. The lower set of graphs were obtained in the same manner for the same frequency as the upper graphs except these graphs are for vertical polarization.

Finally, the fourth page of graphs are the results of the azimuthal angle-of-arrival data for 410 MHz, which were obtained in the same manner as the 230 MHz data.

The shape of the curves for the 230 MHz, horizontally-polarized, azimuthal angle-of-arrival data obtained 25 m above ground and the 410 MHz horizontally-polarized data obtained at 19 m above ground are essentially identical to the antenna patterns obtained over the antenna range for the same antennas.
